The economic impacts of the foreign direct investments: panel estimation by sectors on the case of Macedonian economy

Abstract: This paper elaborates economic impacts of foreign direct investments (FDI) on the case of Macedonian economy. Most developing countries consider FDI a vital source for their development. Anyway, it is quite difficult to measure the economic effects of FDI on the host country, having in mind their numerous direct and indirect effects. Besides the amount of FDI inflows, economic benefit will also depend on their structure. Based on a panel regression technique, FDI impact on GDP, export and employment on the case of Macedonian economy have been estimated, taking into account their structural dimension. The main conclusion of the analysis is that FDI inflows were an important factor for GDP growth and export performances of the Macedonian economy. On the other hand, the FDI impact over employment is negative mainly due to the low level of green field investments and non attractiveness of the labour intensive industry for the foreign investors. These findings regarding the type and sector distribution of FDI inflows are very important for the policy makers and imply a need for a strategic approach in this field.

Key words: foreign direct investments, tradable sector, non tradable sector, economic growth, export, employment.

JEL classification: E22, E24, C23.
1. Introduction

This research paper focuses on the economic impact of foreign direct investments (FDI) on the domestic economy. FDI are usually listed among the most important factors for economic growth of transition economies, considering their numerous direct and indirect effects on domestic economy. Besides FDI inflows, what is important for growth is their sector structure and the type of FDI that could significantly influence the future performances of the economy.

On average, FDI net inflows in the Macedonian economy were relatively lower compared to some other advanced transition economies. It goes in line with relatively lower growth rate in the Macedonian economy, a traditionally high trade deficit and a high and persistent unemployment rate. Based on a panel regression technique, FDI impacts on GDP, export and employment on the case of Macedonian economy have been estimated. The final aim of this analysis is to detect whether the structure of FDI by sectors influenced macroeconomic performance of the Macedonian economy in the past. In addition, it should communicate an important message about this specific feature when attracting the FDI in the future.

The paper first gives a theoretical overview of FDI impacts on economic growth and the literature overview. The next section is about stylized facts on the Macedonian economy, followed by presentation of analytical approach for the empirical research on the case of Macedonian economy, as well as interpretation of the results. The last section concludes with the findings.

2. Theoretical overview of FDI impacts on economic growth

In the analysis of FDI in theory, but also in practice, there is a distinction between their importance as a source of financing within the capital account of the balance of payment and their impact on investments in a domestic economy.

FDI are an alternative source of financing of a domestic economy, with the main advantage of being stable and with a small probability of reversible process. Besides the direct financial inflow, quite often the induced impacts over external financing framework are even greater. In general, FDI inflows reflect investors’ perception about macroeconomic developments and potential growth of an economy. Therefore, the induced impacts could be seen as additional borrowings on the international market, additional funds from the mother company or retained earnings of an FDI-based company. It is possible that those induced finan-
cial flows could even reach the amount of the initial FDI inflow. In this respect, the retained earnings are of crucial importance. They could be repatriated to the foreign investor’s country, but in case they are retained within the company, they are considered as an additional FDI inflow.

FDI are considered as an alternative financing source in addition to the domestic sources, which sometimes could be at a higher price, considering the fact that the profit rate could be higher than the domestic lending interest rates. Higher costs could also arise from the higher amount of profit transferred abroad than the retained earnings or even relative to the initial investment. Companies established or owned by foreign investors could also influence external trade as well as indebtedness of an economy. The Companies based on FDI that are export oriented or enabling imports substitution, have positive impacts on the trade balance of the economy. On the other hand, companies that are import oriented or using borrowings from their parent companies or other external sources could have potential negative impacts on domestic economy.

FDI impacts on investments in the domestic economy are significantly higher comparing to those of other capital flows. Besides evident direct FDI effects on investments, there are so-called indirect effects that can be positive (crowding in) or negative (crowding out). Besides the transfer of new technologies, expertise and good practices with FDI inflows, the positive crowding in effects of FDI appear when FDI generate new investments by other domestic companies, where the relationship input - finished goods or inversely could be set up. Actually, domestic contractors rely heavily on foreign companies that could ensure markets and modern technology. The crowding out effects could arise on the financial markets or on the goods and services market. These are cases when foreign companies are financing their activities from limited domestic savings, influencing towards increase in the domestic interest rates and therefore the cost of financing of domestic companies. In addition, foreign companies are potential competition to the domestic companies on the goods and services market. Anyway, these negative effects to a large extent depend on the secondary impacts (there is possibility that domestic companies under pressure by the competition will increase productivity or reorient towards industry with comparative advantages).

In general, there are two transmission channels through which FDI influence technological development, capital stock and generate economic growth. When a multinational corporation, which usually leads research activities in its field of operation, starts up a new production capacity abroad, this means implementation of new technology in the host country. If this new technology is used for production of capital goods, it will increase the capital stock in the domestic econo-
my, contributing to the enhanced economic growth in the long run, which is the
direct transmission channel. The indirect transmission channel is related to the
transfer of managerial expertise and know-how, which also stimulate technologi-
cal progress and economic growth. FDI could also generate secondary impulses
over other domestic companies to apply new technologies (technologies disper-
sion and transfer of knowledge effect).

This short overview of FDI impacts confirms that the scheme of implications
channels is really large and an eventual cost-benefit analysis could be extremely
complex.

2.1. Literature review

Most developing countries consider FDI a vital source for development. However,
the economic effects of FDI are very difficult to measure accurately given that
growth depends on many factors whose effects are difficult to disentangle, and
given that FDI itself affects several of these factors. As a consequence, the analysis
of the effects of FDI resorts to one of two general approaches. The first is econo-
metric analysis of the relationships between inward FDI and various measures
of economic performance, and the second is a qualitative analysis of particular
aspects of FDI contribution. The econometric analysis of FDI and development
is of long standing, but its conclusions sometimes remain unclear. Some analyses
show a positive impact while others remain agnostic. On the other hand, the
qualitative analysis of FDI is more appealing and practical. The premise is that
FDI offer host countries a mixture of positive and negative effects. The challenge
is to disentangle these effects, taking measures to maximize the first ones and
minimize the others.

A compilation of recent literature on theory and measurement issues of FDI,
structural issues related to the impact on FDI, as well as some analytical and
policy issues can be found in Bora (2002). In-depth analysis of selected topics
related to FDI can be found in different UNCTAD publications. Also, a list of
World Bank’s papers and case studies deal with the following general topics: FDI
impact on growth, trade flows and employment; skills and technology diffusion
via FDI; linkages with domestic companies, etc. The paper by Benacek, Gronicki,
Holland, Sass (2000) is a methodological paper that points to the benefits and
pitfalls of surveys and econometric analysis as two main sources of information.
The authors consider how each of these two sources can contribute to the field of
research, whether they give us complementary or contradictory information and
how this information can be best exploited. They conclude that the findings of econometric studies tend to support survey results.

Jevcak, Setzer, Suardi (2010) analyzed FDI inflows in 10 new EU member countries (from the 2004 EU enlargement), taking into account the specific features of the emerging economies and also pointing out the importance of the FDI structure. The capital inflows to this group of countries were driven by the country-specific factors and also by the global driving forces. One of the conclusions of this paper is that stronger growth and higher interest rates tend to be associated with the larger capital inflows. Anyway, the authors found that a large part of foreign capital in the analyzed countries was directed towards the non-tradable sector, implying lower contribution to productivity growth and export potential. In addition, a high dependence on large foreign capital inflows could be a source of potential vulnerability of the economy in case of a change in the environment and risk perception (evident during the recent crisis).

This paper should contribute to both general approaches - the econometric analysis of the relationships between inward FDI and GDP and export performances, and the qualitative analysis of various aspects of FDI contribution to the performances of the Macedonian economy, therefore being complementary to the studies on FDI in the transition economies. A specific contribution of this research is the structural dimension of the analysis.

3. Stylized facts about FDI in the Macedonian economy

FDI inflows are considered as ones of the main driving forces of the transition economies. The average FDI net inflows in the Macedonian economy in the period 1999 – 2010 were about 4% of GDP, which is relatively lower compared to some other transition economies (the Czech Republic, Slovakia, Bulgaria, the Baltic countries). This could be explained by various reasons. Potential foreign investors are sensitive to numerous factors when making decision about investing abroad, starting from the market size, economic developments and general prospects for growth of the economy, and going further to business climate, overall infrastructure, regulatory and administrative issues. It must be noted that FDI inflows were quite stronger in the period 2006-2008, that coincide with a stronger GDP growth in these years.
The analysis of the FDI stocks by sectors has shown that FDI inflows in the non-tradable sector were higher compared to those in the tradable sector, therefore contributing to a higher and faster growing GDP in the non-tradable sector. Within the non-tradable sector, the largest portion of FDI inflows was in the telecommunication sector.
The higher absorption of FDI by the non-tradable sector contributed to a higher average productivity growth in this sector relative to the tradable sector. Considering a higher employment in the non-tradable sector, the stronger productivity growth in this sector could be related to the new technology based on the FDI inflows.

Graph 5: Productivity in the non-tradable sector

Graph 6: Productivity in the tradable sector

Source: NBRM.

When analyzing the tradable sector, it is important to mention that the export structure of the Macedonian economy is dominated by metal and textile products, followed by food, oil derivatives, mining and chemical industry products. FDI inflows within the tradable sector are mostly concentrated in the metal and food industry, followed by oil derivatives, chemical industry and mining. Among the industrial exporting sectors, only the textile industry is not strongly related to the FDI (although there are some investments of small size). Obviously, the data evidence confirms the importance of FDI for the export capacity of the economy.
The employment analysis by industrial sectors (according to the Labour Force Survey) has shown that employment in the sectors where most of the FDI have been concentrated was stagnant or declining, with some exceptions like the chemical industry, where positive trend is present. In this regard, it is very important to distinguish the role of the privatization based FDI relative to the Greenfield FDI, - the latter supporting the increase in employment in the economy.

Source: SSO, NBRM.
Due to the breakage of the time series for the FDI by sectors\(^1\), the analysis could not be extended for the recent times (it remains as a challenge for the future).

### 4. Empirical analysis

This research focuses on empirical findings on FDI impacts on GDP, export and employment in the Republic of Macedonia in the period 2001 - 2007, by using the panel estimation. The advantage of the panel estimation relative to the alternatives is the time and space dimension. The last one refers to groups within the panel, which in this case are sectors or groups of sectors based on the National Classification of the Economic Activities - NACE\(^2\). This dimension enables taking into account a different level of heterogeneity between the groups. Within estimations, FDI are considered as the exogenous variable, thus the analysis does not incorporate economic or political factors that influence FDI.

The results of this research are based on two types of the panel estimation – the panel with fixed effects and the panel with random effects.

The model with **fixed effects** gives the opportunity to control for all stable features of the groups, including the non-measurable ones (non-measurable heterogeneity). In the general specifications of such models, the non-measurable heterogeneity is given with \(a_i\).

\[
Y_{it} = \beta_0 + \beta_1 x_{1it} + \beta_2 x_{2it} + \ldots + \beta_k x_{kit} + a_i + u_{it}
\]

The time dimension of the model variables is given with \(t\), while \(i\) stands for different groups in the panel. Thus, \(a_i\) is without \(t\) referring to its fixed effect through the time. On the other hand, \(u_{it}\) as error in the model vary by \(t\) and \(i\), both, representing non measurable factors influencing the dependant variable.

The models with **random effects** apply an additional assumption in the estimation. Starting from the panel with fixed effects and the specified equation, in the

---

1 At the time of writing the paper, a consistent time series of FDI by sectors were available up to 2007, according to NACE 1. From May 2012, the data for FDI by sectors for the period 2009 - 2011 are available, according to NACE 2. These data are produced by the NBRM.

2 NACE is classification of the economic activities in the European Union that is used by the SSO in the Republic of Macedonia, for compiling, processing and dissemination of statistical data. The NACE is also used for classification of the legal entities by sectors they perform, for business registers and other administrative purposes. NACE is composed of four levels: sector, section, group and class.
models with random effects the additional assumption is that $a_i$ is uncorrelated with each of the explanatory variables $1...k$ in each time period $t$, $\text{Cov}(x_{kit}, a_i)=0$. In the models with fixed effects, $a_i$ as an individual fixed effect does not mean that it is not random variable, but it means that the correlation between this term and explanatory variables is allowed. In addition, within the models with random effects, $a_i$ is included in the error of the model. Therefore, these models have the so-called composite error: $\nu_{it} = a_i + u_{it}$. The general specification of the estimated model with random effects is the following:

$$Y_{it} = \beta_0 + \beta_1 x_{1it} + \beta_2 x_{2it} + \ldots + \beta_k x_{kit} + \nu_{it}$$

The composite error is serially correlated through time. Thus, the random effects method uses this serial correlation of the composite error within the GLS (Generalized Least Square) framework.

5. Estimation of FDI impact on GDP

5.1. Data and model

The initial point for analysis of FDI impact on GDP is the well-known Cobb-Douglass production function enlarged with FDI and the use of panel estimation.

$$\text{GDP} = \beta_0 * K^{\beta_1} * K^{\beta_2} * \text{FDI}^{\beta_3}$$

In addition, we use sectoral breakdown of the respective variables. Therefore, $K$ is for investments in fixed assets by the sector in the current year, $L$ is for employees by sectors according to the Labour Force Survey, and FDI is for FDI stock by sectors. Under the panel regression, each variable is transformed in logs.

$$\ln(\text{GDP}) = h \beta_0 + \beta_1 \ln(K) + \beta_2 \ln(L) + \beta_3 \ln(\text{FDI})$$

The reason why the FDI variable is the stock variable is to take care about extended effects of FDI on GDP, having in mind that some positive FDI implications need some time to reflect over the real economy (transfer of skills, expertise)\(^3\). If FDI flows are used, a potential problem in the analysis could arise in case that there could be an extraordinary high inflow in one year, while in the following years such high inflows are missing. In case that FDI flows are used, it means

that the effect of the high inflow for all following years will be zero, neglecting the very high presence of foreign capital already being invested in the country. In addition, the FDI variable refers to inward FDI (outward investments in the transitional period almost do not exist).

Regarding the time horizon, the annual data for the period 2001 - 2007 are used, due to the fact that data on employees by sectors according to the NACE are available from 2001, while FDI by sectors were available up to 2007.

Data on GDP and investments in fixed assets are provided in the same aggregation by sectors as in Table 1, by the State Statistical Office (SSO). Data on employees are from the Labour Force Survey of the SSO and data on FDI are from the NBRM. All the data are in current prices and they are deflated by the industrial producer price index (PPI, base: 2005) for the analysis purposes.

The theoretical framework assumes cointegration relationship between GDP, capital stock (domestic and foreign capital) and employment. We also confirm cointegration in the data with Pedroni test (1999, 2004). This test has been used because all inclusive seven test statistics assume independence of the groups in the panel. Therefore, this test enables to capture the individual variability within the groups in the panel.

Within the model, it is necessary to consider the issue of endogeniety and multicollinearity. We assume that FDI influence economic growth, but also that higher GDP would also attract more FDI, meaning that FDI are not entirely exogenous. At the same time, FDI are a complementary part of the domestic investments (FDI in fixed assets are included within the investments in fixed assets category of the national accounts statistics), pointing to the fact that these two types of capital investments are not completely independent (multicollinearity problem). However, considering the valid cointegration relationship, endogeniety and multicollinearity do not play any role, thus the regression coefficients of the
explanatory variables are not statistically bias and they can be used as a basis for making conclusions.

Based on the data, we cannot extract exact information about the causal relationship between FDI and economic growth, considering the need for a higher number of observations within the groups of the panel. Therefore, the standard Granger test of causality cannot be implemented. Anyway, the literature clearly demonstrates that FDI support the capital accumulation and technological progress and consequently economic growth. On the other hand, economic growth is only one of numerous variables that influence FDI inflows. Thus, we could assume that FDI impact on economic growth is larger than the opposite relationship. At the same time, the analysis cannot ignore that FDI and GDP both are influenced by other factors (political stability, country risk, expectations), that also stand for the domestic investments.

5.2. Model results

The estimation of the equation is done by using the OLS method (ordinary least squares). A panel of fixed effects in the groups has been specified (fixed effects in the time dimension are insignificant). There is a positive and statistically significant coefficient of the FDI variable, showing that with 1% growth of the FDI stock, ceteris paribus, there is a 0.23% GDP growth in the current year. The coefficient of the investments in fixed assets (K) is positive and amounts to 0.14 and the labour force coefficient (L) is 0.69 (Table 2).

Given the model results, we can additionally compute the income shares of the input factors backwards as implied by the estimated regression coefficients, i.e. we can compute the size of the implied income share of foreign capital holders, and that of domestic capital holders.

The size of the implied income shares for domestic and foreign capital in the total capital can be computed using the following formulas as well as using the results reported in Table 2 above.
\[ \alpha = \frac{\hat{\beta}_1}{1 + \hat{\beta}_1 + \hat{\beta}_3} \quad \text{and} \quad \beta = \frac{\hat{\beta}_3}{1 + \hat{\beta}_1 + \hat{\beta}_3} \]

Table 3: Income shares of the input factors to production

<table>

</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>0.17</td>
<td>0.10</td>
<td>0.27</td>
<td>0.73</td>
</tr>
</tbody>
</table>

According to Table 3, total capital income amounts to 27% of GDP compared to 73% which goes to labour. These results concerning total capital income and labour income are absolutely in line with the broad empirical growth literature for transition economies. FDI in our case accounts for about two thirds of total capital income. According to Neuhaus (2006), this share for transition countries accounts for about one fourth of total capital income. This finding points to the fact that FDI in Macedonia, although with a relatively higher share in a relatively modest total capital stock, in our assessment, produce relatively limited investment spillovers beyond the direct increase in capital stock through linkages with local firms (this is usually the case when foreign corporations use imported inputs for their activities which is broadly the case with the biggest foreign investors in the Macedonian manufacturing sector).

6. Estimation of FDI impacts over export

6.1. Data and model

This part of the analysis is aimed to value the FDI effects on exports and to answer the question whether FDI stimulate exports. Although the accumulated FDI per capita in Macedonia is lower compared to other transition economies, the export developments imply that FDI have been making important contribution to the export promotion. As a support to this conclusion, there is a detailed analysis on the FDI and export relationship, where also the effects of other important variables influencing the export are taken into consideration. Within the export analysis, only tradable goods sectors are considered (services and agriculture are excluded). It actually means that the analysis focuses on the impact of FDI stock in the mining and manufacturing industry on the export of these sectors.
The annual data for the period 2002 - 2007 have been used in the analysis. The analyzed period was conditioned by the data availability for export classification by sectors since 2002, which were linked to the FDI data by sectors available up to 2007. The analysis includes 17 industrial branches (3 branches from the mining and quarrying and 14 branches from manufacturing industry) based on NACE\textsuperscript{4}. Furthermore, for the needs of the analysis these 17 branches are classified into 10 groups\textsuperscript{5} (table 4).

<td></td>
</tr>
</tbody>
</table>

\textsuperscript{4} According to the NACE, manufacturing industry includes subsections 15 to 37, and the mining and quarrying include subsections number 10, 13 and 14.

\textsuperscript{5} The branches 17 and 18 compose one group, branches 20-22 are another group, branches 27 and 28 are the third group, branches 34 and 35 are the fourth group, and the fifth group are the branches within the mining and quarrying number 10, 13 and 14. The remaining five branches compose the other five groups in the panel.
The economic impacts of the foreign direct investments

The data for the export, industrial production (volume) index, number of employees (based on the Labour Force Survey) and the industrial producer price index are from the State Statistical Office. The productivity index is calculated as the ratio of the industrial production index to the index of the employees for each group in the panel (with 2005 as the base year in both cases). The data on exports and FDI by groups in the panel were converted in the national currency (MKD) and deflated by the aggregate producer price index (with 2005 as the base year).

The following panel regression has been estimated:

\[ \ln (EX_{i,t}) = \beta_0 + \beta_1 \ln (PD\_INDEX_{i,t}) + \beta_2 \ln (FDI_{i(t-1)}) \] (3)

The method of random effects under panel estimation has been used. In the equation the export is a dependent variable, while the productivity index and FDI stock are explanatory variables. All variables are in logs. FDI are with a one-year lag in the panel regression in line with the assumption of additional period needed to see their effects. The time lag in FDI also enables to overcome the problem of potential simultaneity in the export and FDI. In addition, by using the FDI stock, potential indirect and extended effects of the FDI are also included.

It is important to mention that the foreign effective demand as potentially important variable is not included in the model. The reason is that the foreign effective demand, calculated as a weighted average of the real GDP growth of the main trading partners of the Republic of Macedonia in line with their share in the Macedonian export, has proved statistically irrelevant in the model. Its insignificance could be possibly due to important differences in the export demand by types of industry. However, the impacts of external demand, as well as of other variables that are not included, are considered through random individual effects of the different industrial branches or groups within the panel, enabling consistency in the estimation.

Productivity as a measure of the export competitiveness of the industries is included in the model, although there is a potential problem, identified in the theory of the international trade, of eventual causal relationship between the export and productivity. In order to account for the eventual simultaneity, the 2SLS (Two Stage Least Squares) method of estimation and the instrumental variables for productivity have also been used. As instrumental variable for the productivity, the employment proved as an adequate choice, considering the fact that the productivity increase in the period 2002 - 2007 was mainly due to a decline in employment in the mining and manufacturing industry. On the other hand, the productivity increase could arise from investments in new technologies and the
transfer of knowledge coming with FDI. Therefore, there is also an economic reason in using FDI as the instrumental variable for productivity. The solution for the final selection of instruments was done through the following panel regression:

\[
\ln(PD\_INDEX_{it}) = \beta_0 + \beta_1 \ln(EMP\_INDEX_{it}\text{(-1)}) + \\
\beta_2 \ln(EMP\_INDEX_{it}\text{(-2)}) + \beta_3 \ln(FDI_{it}\text{(-4)})
\] (4)

6.2. Results of the models

The equation (4) provides empirical evidence that FDI positively and significantly influence productivity (Table 5). When employment is used as the only instrumental variable (excluding FDI from the list of instruments), productivity in the export equation (3) gets a negative and insignificant coefficient, confirming that productivity increase induced by job cuts in the mining and manufacturing industry did not promote exports. It means that the impact of productivity growth on export growth comes out only through the channel of FDI influence on productivity (implementation of new technologies, transfer of know-how, management skills and expertise).

7. FDI impact on employment - model and results

Based on the data explained in the previous section, an additional analysis has been done of the FDI impact on the employment level in the mining and manufacturing industry. Employment has been regressed on the FDI stock by industrial branches classified in groups as given in Table 3. The analysis is based on the following model with random individual effects by groups in the panel:

\[
\ln(EMP_{it}) = \beta_0 + \beta_1 \ln(FDI_{it})
\]

(5)

The results of the estimation are summed up in Table 6. The main interest is the total influence (positive and negative) of the FDI over the employment in the mining and manufacturing industry. The empirical results have shown to negative and statistically significant total influence of FDI over employment. Thus, the sector of mining and manufacturing industry where FDI inflow had an upward trend in the period 2002-2007, is lagging behind jobs creation. There are several reasons why FDI accumulation in these industries is not accompanied by employment growth. First, the type of FDI is very important. In greenfield investments there is a higher opportunity for job creation than in acquisitions or takeovers of the existing domestic companies. Second, FDI in Macedonia are mainly concentrated in the capital intensive industries, which implies limitations to the extent of the job creation. Third, the larger portion of the labour force is employed in the textile industry, as a labour intensive industry, where FDI are small.

Besides the direct impact, the indirect FDI impact over employment is also important. It could be either positive or negative, depending on the balance between the crowding-in effects (creation of new markets for the local companies) and crowding-out effects of FDI (competition to the local companies). The local links of foreign investors in Macedonia are quite limited, having in mind that the largest foreign investors mainly provide the inputs for their production process from abroad. This stands primarily for the metal and textile industry, while food industry is more oriented towards the use of the local inputs, but a broad picture is that FDI capacities in the Macedonian manufacturing industry are highly dependent on the imported inputs.
Anyway, even if we assume a positive indirect effect, the total FDI effect (both direct and indirect) on employment is negative mainly due to a low level of greenfield investments and non-attractiveness of the labour intensive industry to the foreign investors. The model (5) empirically confirms that 1% growth of the FDI stock causes a decline in employment of 0.16%.

8. Conclusion

This research focuses on the empirical analysis of the economic impacts of the foreign direct investments on the domestic economy. For this purpose, on the case of Macedonian economy, the FDI impact on GDP, export and employment have been estimated based on the panel regression technique. The analysis has shown that the sector structure and the type of FDI significantly influence the economic performances of the economy.

Besides the fact that average FDI net inflows in the Macedonian economy were relatively lower compared to some other transition economies, it is shown that FDI inflows were important factor for GDP growth and export performances of the Macedonian economy. The impact on export was probably limited having in mind that a large portion of FDI was allocated to the non-tradable sector. It is interesting to mention that a positive impact on export was stronger than the impact on the overall GDP. This could mean that the local links of foreign investors in Macedonia are quite limited, having in mind that the largest foreign investors mainly provide the inputs for their production process from abroad. Therefore, the indirect positive FDI impact could be stated as limited. Anyway, the empirical analysis has proven a positive contribution of FDI to productivity, mainly through the implementation of new technologies, the transfer of know-how, management skills and expertise. On the other hand, the FDI impact on employment is negative mainly due to the low level of greenfield investments and non attractiveness of the labour intensive industry for foreign investors.

This analysis provides important information for the policy makers. The FDI entrance in the tradable sector and export oriented industries should have a priority from the viewpoint of the economic performances. In addition, the focus should be on attracting greenfield investments that could contribute to the reduction of unemployment. For the overall impact of FDI on the economy it is also important to stimulate the links and cooperation of the FDI-based companies with the local companies.
